

2

FLOW CONTROL

So you know the basics of individual instructions and that a program is just a series of instructions. But the real strength of programming isn't just running (or *executing*) one instruction after another like a weekend errand list. Based on how the expressions evaluate, the program can decide to skip instructions, repeat them, or choose one of several instructions to run. In fact, you almost never want your programs to start from the first line of code and simply execute every line, straight to the end. *Flow control statements* can decide which Python instructions to execute under which conditions.

These flow control statements directly correspond to the symbols in a flowchart, so I'll provide flowchart versions of the code discussed in this chapter. Figure 2-1 shows a flowchart for what to do if it's raining. Follow the path made by the arrows from Start to End.

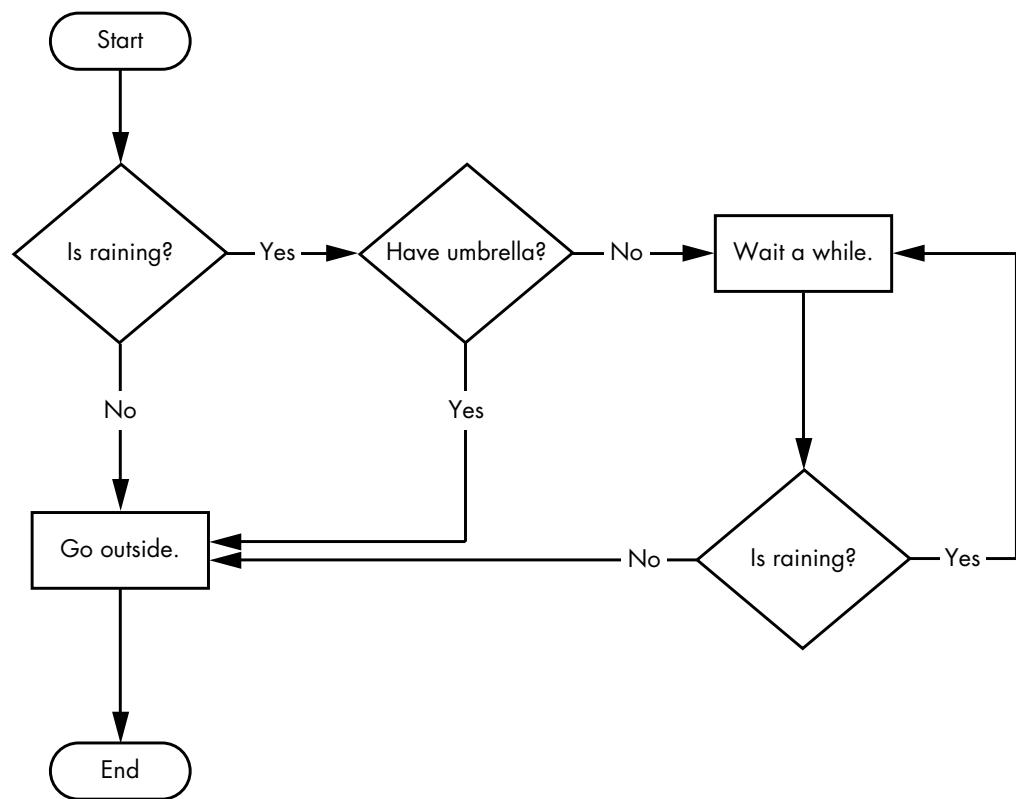

Figure 2-1: A flowchart to tell you what to do if it is raining

In a flowchart, there is usually more than one way to go from the start to the end. The same is true for lines of code in a computer program. Flowcharts represent these branching points with diamonds, while the other steps are represented with rectangles. The starting and ending steps are represented with rounded rectangles.

But before you learn about flow control statements, you first need to learn how to represent those *yes* and *no* options, and you need to understand how to write those branching points as Python code. To that end, let's explore Boolean values, comparison operators, and Boolean operators.

Boolean Values

While the integer, floating-point, and string data types have an unlimited number of possible values, the *Boolean* data type has only two values: `True` and `False`. (Boolean is capitalized because the data type is named after mathematician George Boole.) When typed as Python code, the Boolean values `True` and `False` lack the quotes you place around strings, and they always start with a capital *T* or *F*, with the rest of the word in lowercase. Enter the following into the interactive shell. (Some of these instructions are intentionally incorrect, and they'll cause error messages to appear.)

```
❶ >>> spam = True
>>> spam
True
❷ >>> true
Traceback (most recent call last):
  File "<pyshell#2>", line 1, in <module>
    true
NameError: name 'true' is not defined
❸ >>> True = 2 + 2
SyntaxError: assignment to keyword
```

Like any other value, Boolean values are used in expressions and can be stored in variables ❶. If you don't use the proper case ❷ or you try to use True and False for variable names ❸, Python will give you an error message.

Comparison Operators

Comparison operators compare two values and evaluate down to a single Boolean value. Table 2-1 lists the comparison operators.

Table 2-1: Comparison Operators

Operator	Meaning
==	Equal to
!=	Not equal to
<	Less than
>	Greater than
<=	Less than or equal to
>=	Greater than or equal to

These operators evaluate to True or False depending on the values you give them. Let's try some operators now, starting with == and !=.

```
>>> 42 == 42
True
>>> 42 == 99
False
>>> 2 != 3
True
>>> 2 != 2
False
```

As you might expect, == (equal to) evaluates to True when the values on both sides are the same, and != (not equal to) evaluates to True when the two values are different. The == and != operators can actually work with values of any data type.

```
>>> 'hello' == 'hello'
True
>>> 'hello' == 'Hello'
False
>>> 'dog' != 'cat'
True
>>> True == True
True
>>> True != False
True
>>> 42 == 42.0
True
❶ >>> 42 == '42'
False
```

Note that an integer or floating-point value will always be unequal to a string value. The expression `42 == '42'` **❶** evaluates to `False` because Python considers the integer `42` to be different from the string `'42'`.

The `<`, `>`, `<=`, and `>=` operators, on the other hand, work properly only with integer and floating-point values.

```
>>> 42 < 100
True
>>> 42 > 100
False
>>> 42 < 42
False
>>> eggCount = 42
❶ >>> eggCount <= 42
True
>>> myAge = 29
❷ >>> myAge >= 10
True
```

THE DIFFERENCE BETWEEN THE == AND = OPERATORS

You might have noticed that the `==` operator (equal to) has two equal signs, while the `=` operator (assignment) has just one equal sign. It's easy to confuse these two operators with each other. Just remember these points:

- The `==` operator (equal to) asks whether two values are the same as each other.
- The `=` operator (assignment) puts the value on the right into the variable on the left.

To help remember which is which, notice that the `==` operator (equal to) consists of two characters, just like the `!=` operator (not equal to) consists of two characters.

You'll often use comparison operators to compare a variable's value to some other value, like in the `eggCount <= 42` ❶ and `myAge >= 10` ❷ examples. (After all, instead of typing `'dog' != 'cat'` in your code, you could have just typed `True`.) You'll see more examples of this later when you learn about flow control statements.

Boolean Operators

The three Boolean operators (and, or, and not) are used to compare Boolean values. Like comparison operators, they evaluate these expressions down to a Boolean value. Let's explore these operators in detail, starting with the and operator.

Binary Boolean Operators

The and and or operators always take two Boolean values (or expressions), so they're considered *binary* operators. The and operator evaluates an expression to True if *both* Boolean values are True; otherwise, it evaluates to False. Enter some expressions using and into the interactive shell to see it in action.

```
>>> True and True
True
>>> True and False
False
```

A *truth table* shows every possible result of a Boolean operator. Table 2-2 is the truth table for the and operator.

Table 2-2: The and Operator's Truth Table

Expression	Evaluates to...
True and True	True
True and False	False
False and True	False
False and False	False

On the other hand, the or operator evaluates an expression to True if *either* of the two Boolean values is True. If both are False, it evaluates to False.

```
>>> False or True
True
>>> False or False
False
```

You can see every possible outcome of the or operator in its truth table, shown in Table 2-3.

Table 2-3: The or Operator's Truth Table

Expression	Evaluates to...
True or True	True
True or False	True
False or True	True
False or False	False

The not Operator

Unlike and and or, the not operator operates on only one Boolean value (or expression). The not operator simply evaluates to the opposite Boolean value.

```
>>> not True
False
❶ >>> not not not not True
True
```

Much like using double negatives in speech and writing, you can nest not operators ❶, though there's never not no reason to do this in real programs. Table 2-4 shows the truth table for not.

Table 2-4: The not Operator's Truth Table

Expression	Evaluates to...
not True	False
not False	True

Mixing Boolean and Comparison Operators

Since the comparison operators evaluate to Boolean values, you can use them in expressions with the Boolean operators.

Recall that the and, or, and not operators are called Boolean operators because they always operate on the Boolean values True and False. While expressions like `4 < 5` aren't Boolean values, they are expressions that evaluate down to Boolean values. Try entering some Boolean expressions that use comparison operators into the interactive shell.

```
>>> (4 < 5) and (5 < 6)
True
>>> (4 < 5) and (9 < 6)
False
>>> (1 == 2) or (2 == 2)
True
```

The computer will evaluate the left expression first, and then it will evaluate the right expression. When it knows the Boolean value for each, it will then evaluate the whole expression down to one Boolean value. You can think of the computer's evaluation process for $(4 < 5)$ and $(5 < 6)$ as shown in Figure 2-2.

You can also use multiple Boolean operators in an expression, along with the comparison operators.

```
>>> 2 + 2 == 4 and not 2 + 2 == 5 and 2 * 2 == 2 + 2
True
```

Figure 2-2: The process of evaluating $(4 < 5)$ and $(5 < 6)$ to *True*.

The Boolean operators have an order of operations just like the math operators do. After any math and comparison operators evaluate, Python evaluates the not operators first, then the and operators, and then the or operators.

Elements of Flow Control

Flow control statements often start with a part called the *condition*, and all are followed by a block of code called the *clause*. Before you learn about Python's specific flow control statements, I'll cover what a condition and a block are.

Conditions

The Boolean expressions you've seen so far could all be considered conditions, which are the same thing as expressions; *condition* is just a more specific name in the context of flow control statements. Conditions always evaluate down to a Boolean value, True or False. A flow control statement decides what to do based on whether its condition is True or False, and almost every flow control statement uses a condition.

Blocks of Code

Lines of Python code can be grouped together in *blocks*. You can tell when a block begins and ends from the indentation of the lines of code. There are three rules for blocks.

1. Blocks begin when the indentation increases.
2. Blocks can contain other blocks.
3. Blocks end when the indentation decreases to zero or to a containing block's indentation.

Blocks are easier to understand by looking at some indented code, so let's find the blocks in part of a small game program, shown here:

```
if name == 'Mary':  
    ❶ print('Hello Mary')  
    if password == 'swordfish':  
        ❷ print('Access granted.')  
    else:  
        ❸ print('Wrong password.')
```

The first block of code ❶ starts at the line `print('Hello Mary')` and contains all the lines after it. Inside this block is another block ❷, which has only a single line in it: `print('Access Granted.')`. The third block ❸ is also one line long: `print('Wrong password.')`.

Program Execution

In the previous chapter's *hello.py* program, Python started executing instructions at the top of the program going down, one after another. The *program execution* (or simply, *execution*) is a term for the current instruction being executed. If you print the source code on paper and put your finger on each line as it is executed, you can think of your finger as the program execution.

Not all programs execute by simply going straight down, however. If you use your finger to trace through a program with flow control statements, you'll likely find yourself jumping around the source code based on conditions, and you'll probably skip entire clauses.

Flow Control Statements

Now, let's explore the most important piece of flow control: the statements themselves. The statements represent the diamonds you saw in the flowchart in Figure 2-1, and they are the actual decisions your programs will make.

if Statements

The most common type of flow control statement is the *if* statement. An *if* statement's clause (that is, the block following the *if* statement) will execute if the statement's condition is *True*. The clause is skipped if the condition is *False*.

In plain English, an *if* statement could be read as, "If this condition is true, execute the code in the clause." In Python, an *if* statement consists of the following:

- The *if* keyword
- A condition (that is, an expression that evaluates to *True* or *False*)
- A colon
- Starting on the next line, an indented block of code (called the *if* clause)

For example, let's say you have some code that checks to see whether someone's name is Alice. (Pretend name was assigned some value earlier.)

```
if name == 'Alice':  
    print('Hi, Alice.')
```

All flow control statements end with a colon and are followed by a new block of code (the clause). This if statement's clause is the block with `print('Hi, Alice.')`. Figure 2-3 shows what a flowchart of this code would look like.

Figure 2-3: The flowchart for an if statement

else Statements

An if clause can optionally be followed by an else statement. The else clause is executed only when the if statement's condition is False. In plain English, an else statement could be read as, "If this condition is true, execute this code. Or else, execute that code." An else statement doesn't have a condition, and in code, an else statement always consists of the following:

- The else keyword
- A colon
- Starting on the next line, an indented block of code (called the else clause)

Returning to the Alice example, let's look at some code that uses an else statement to offer a different greeting if the person's name isn't Alice.

```
if name == 'Alice':  
    print('Hi, Alice.')
```

```
else:  
    print('Hello, stranger.')
```

Figure 2-4 shows what a flowchart of this code would look like.

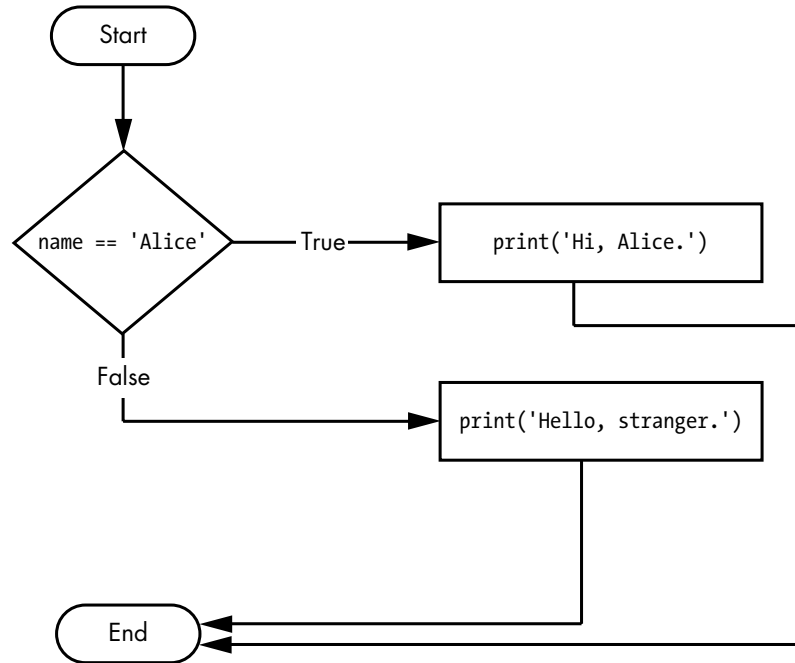

Figure 2-4: The flowchart for an *else* statement

***elif* Statements**

While only one of the `if` or `else` clauses will execute, you may have a case where you want one of *many* possible clauses to execute. The `elif` statement is an “else if” statement that always follows an `if` or another `elif` statement. It provides another condition that is checked only if any of the previous conditions were `False`. In code, an `elif` statement always consists of the following:

- The `elif` keyword
- A condition (that is, an expression that evaluates to `True` or `False`)
- A colon
- Starting on the next line, an indented block of code (called the `elif` clause)

Let’s add an `elif` to the name checker to see this statement in action.

```
if name == 'Alice':  
    print('Hi, Alice.')
```

```
elif age < 12:  
    print('You are not Alice, kiddo.')
```

This time, you check the person's age, and the program will tell them something different if they're younger than 12. You can see the flowchart for this in Figure 2-5.

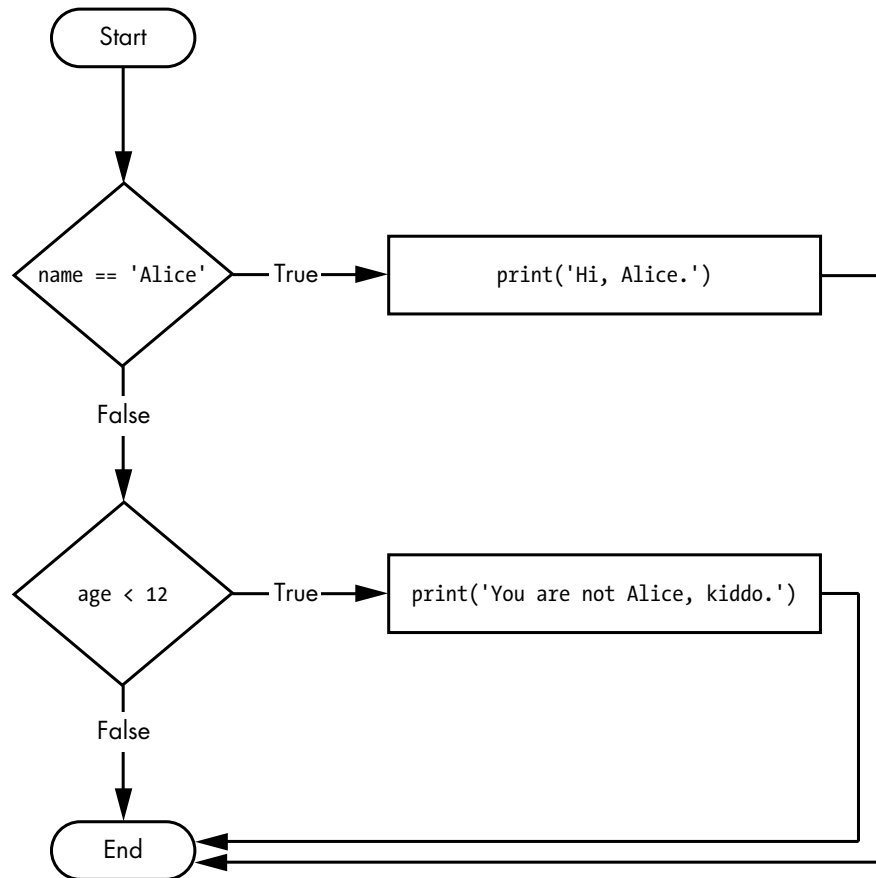

Figure 2-5: The flowchart for an `elif` statement

The `elif` clause executes if `age < 12` is `True` and `name == 'Alice'` is `False`. However, if both of the conditions are `False`, then both of the clauses are skipped. It is *not* guaranteed that at least one of the clauses will be executed. When there is a chain of `elif` statements, only one or none of the clauses will be executed. Once one of the statements' conditions is found to be `True`, the rest of the `elif` clauses are automatically skipped. For example, open a new file editor window and enter the following code, saving it as *vampire.py*:

```
if name == 'Alice':
    print('Hi, Alice.')
elif age < 12:
    print('You are not Alice, kiddo.')
elif age > 2000:
    print('Unlike you, Alice is not an undead, immortal vampire.')
elif age > 100:
    print('You are not Alice, grannie.')
```

Here I've added two more `elif` statements to make the name checker greet a person with different answers based on age. Figure 2-6 shows the flowchart for this.

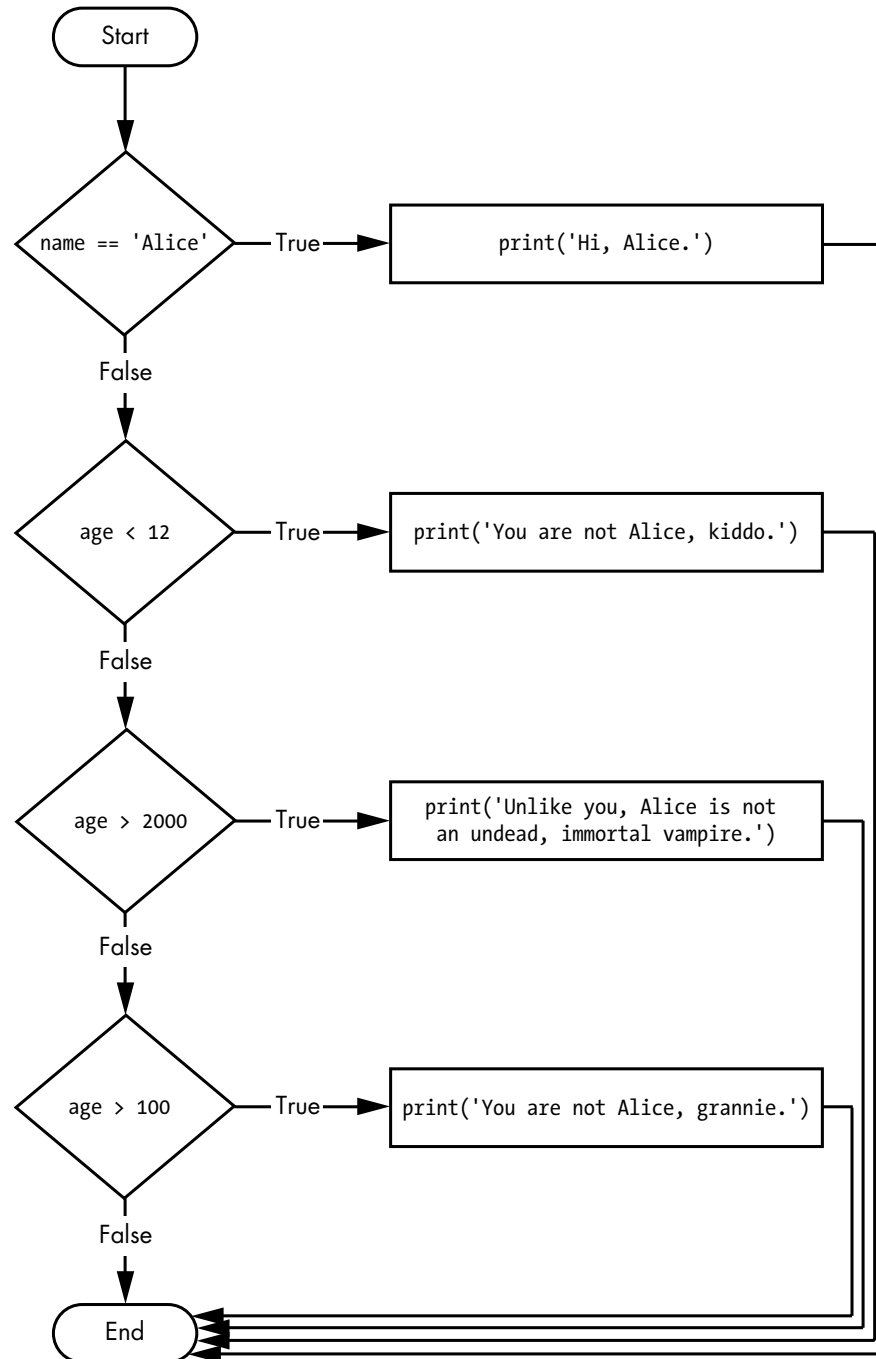

Figure 2-6: The flowchart for multiple `elif` statements in the `vampire.py` program

The order of the `elif` statements does matter, however. Let's rearrange them to introduce a bug. Remember that the rest of the `elif` clauses are automatically skipped once a `True` condition has been found, so if you swap around some of the clauses in *vampire.py*, you run into a problem. Change the code to look like the following, and save it as *vampire2.py*:

```
if name == 'Alice':
    print('Hi, Alice.')
elif age < 12:
    print('You are not Alice, kiddo.')
❶ elif age > 100:
    print('You are not Alice, grannie.')
elif age > 2000:
    print('Unlike you, Alice is not an undead, immortal vampire.')
```

Say the `age` variable contains the value 3000 before this code is executed. You might expect the code to print the string 'Unlike you, Alice is not an undead, immortal vampire.'. However, because the `age > 100` condition is `True` (after all, 3000 *is* greater than 100) ❶, the string 'You are not Alice, grannie.' is printed, and the rest of the `elif` statements are automatically skipped. Remember, at most only one of the clauses will be executed, and for `elif` statements, the order matters!

Figure 2-7 shows the flowchart for the previous code. Notice how the diamonds for `age > 100` and `age > 2000` are swapped.

Optionally, you can have an `else` statement after the last `elif` statement. In that case, it *is* guaranteed that at least one (and only one) of the clauses will be executed. If the conditions in every `if` and `elif` statement are `False`, then the `else` clause is executed. For example, let's re-create the Alice program to use `if`, `elif`, and `else` clauses.

```
if name == 'Alice':
    print('Hi, Alice.')
elif age < 12:
    print('You are not Alice, kiddo.')
else:
    print('You are neither Alice nor a little kid.')
```

Figure 2-8 shows the flowchart for this new code, which we'll save as *littleKid.py*.

In plain English, this type of flow control structure would be, "If the first condition is true, do this. Else, if the second condition is true, do that. Otherwise, do something else." When you use all three of these statements together, remember these rules about how to order them to avoid bugs like the one in Figure 2-7. First, there is always exactly one `if` statement. Any `elif` statements you need should follow the `if` statement. Second, if you want to be sure that at least one clause is executed, close the structure with an `else` statement.

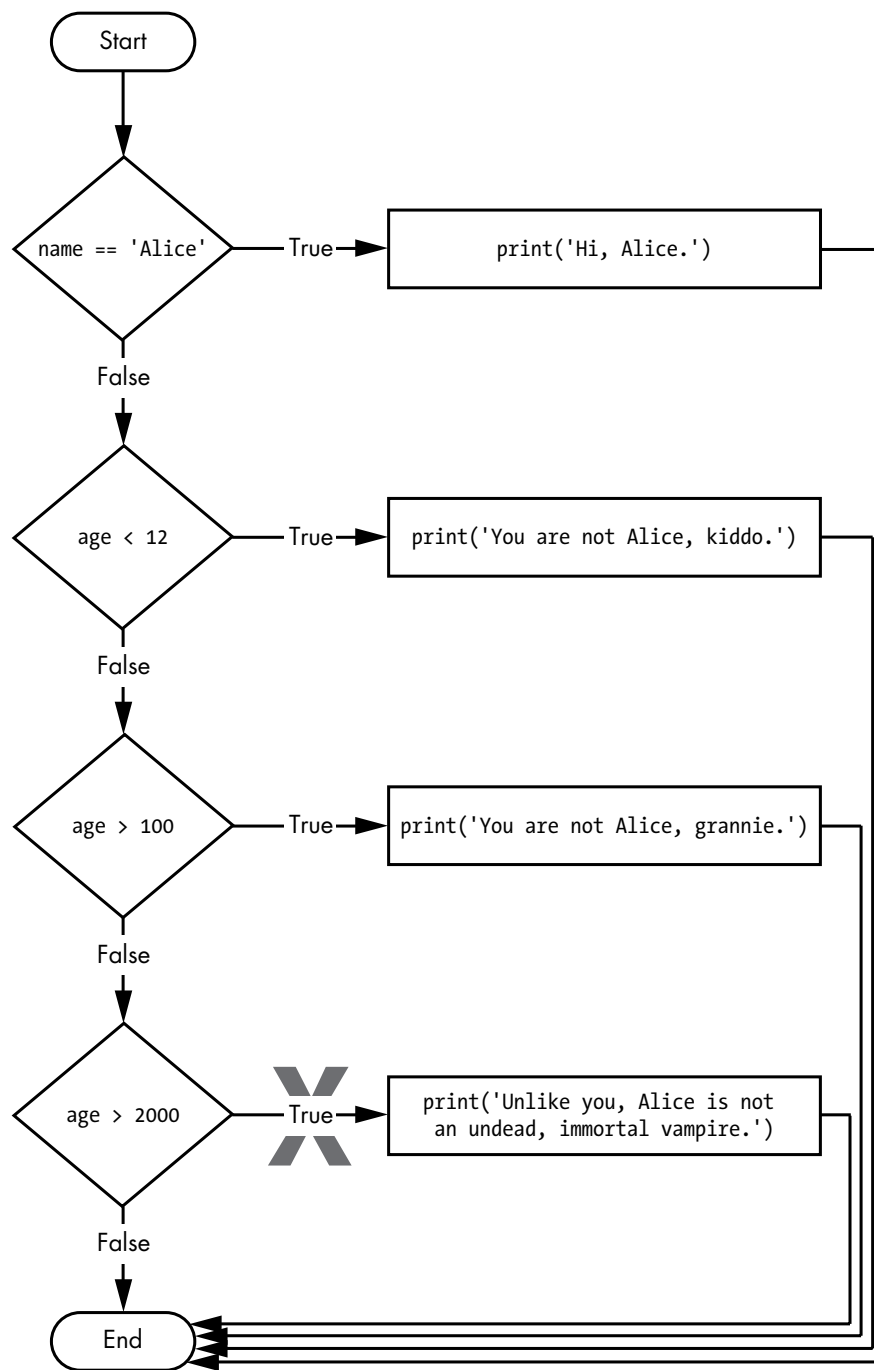

Figure 2-7: The flowchart for the vampire2.py program. The crossed-out path will logically never happen, because if age were greater than 2000, it would have already been greater than 100.

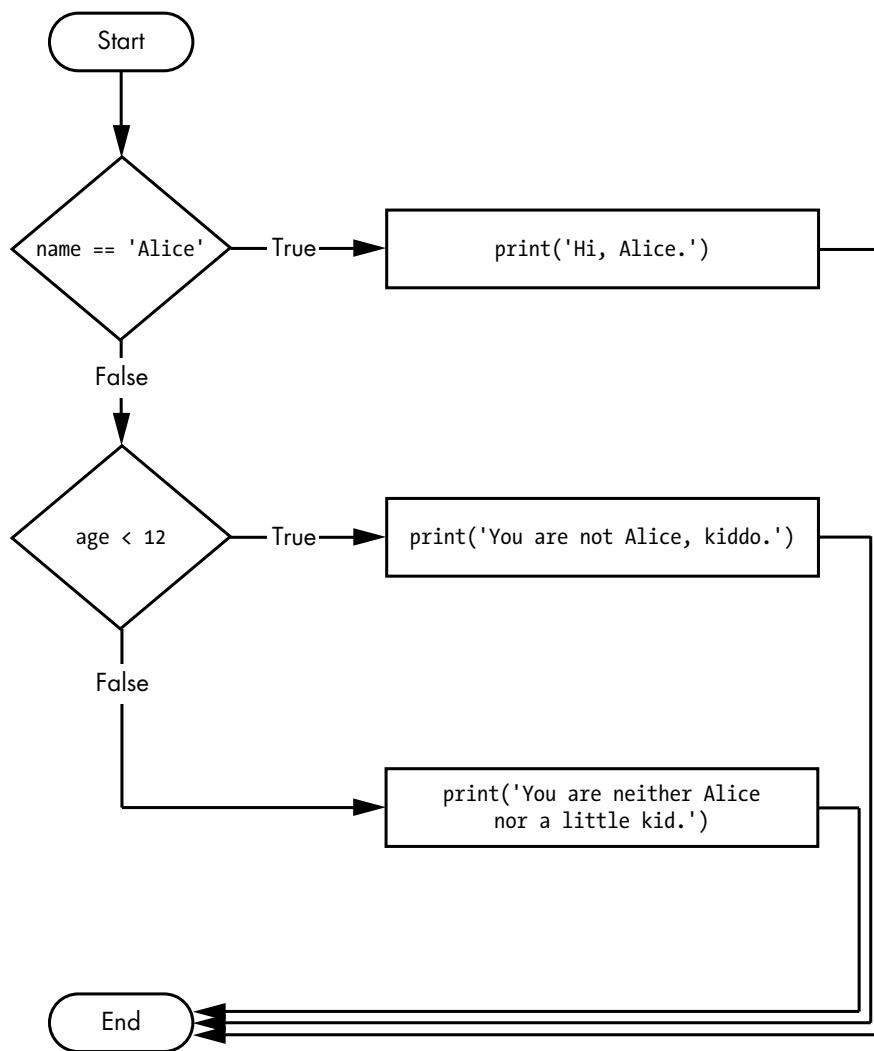

Figure 2-8: Flowchart for the previous `littleKid.py` program

while Loop Statements

You can make a block of code execute over and over again with a `while` statement. The code in a `while` clause will be executed as long as the `while` statement's condition is `True`. In code, a `while` statement always consists of the following:

- The `while` keyword
- A condition (that is, an expression that evaluates to `True` or `False`)
- A colon
- Starting on the next line, an indented block of code (called the `while` clause)

You can see that a `while` statement looks similar to an `if` statement. The difference is in how they behave. At the end of an `if` clause, the program execution continues after the `if` statement. But at the end of a `while` clause, the program execution jumps back to the start of the `while` statement. The `while` clause is often called the *while loop* or just the *loop*.

Let's look at an `if` statement and a `while` loop that use the same condition and take the same actions based on that condition. Here is the code with an `if` statement:

```
spam = 0
if spam < 5:
    print('Hello, world.')
    spam = spam + 1
```

Here is the code with a `while` statement:

```
spam = 0
while spam < 5:
    print('Hello, world.')
    spam = spam + 1
```

These statements are similar—both `if` and `while` check the value of `spam`, and if it's less than five, they print a message. But when you run these two code snippets, something very different happens for each one. For the `if` statement, the output is simply "Hello, world.". But for the `while` statement, it's "Hello, world." repeated five times! Take a look at the flowcharts for these two pieces of code, Figures 2-9 and 2-10, to see why this happens.

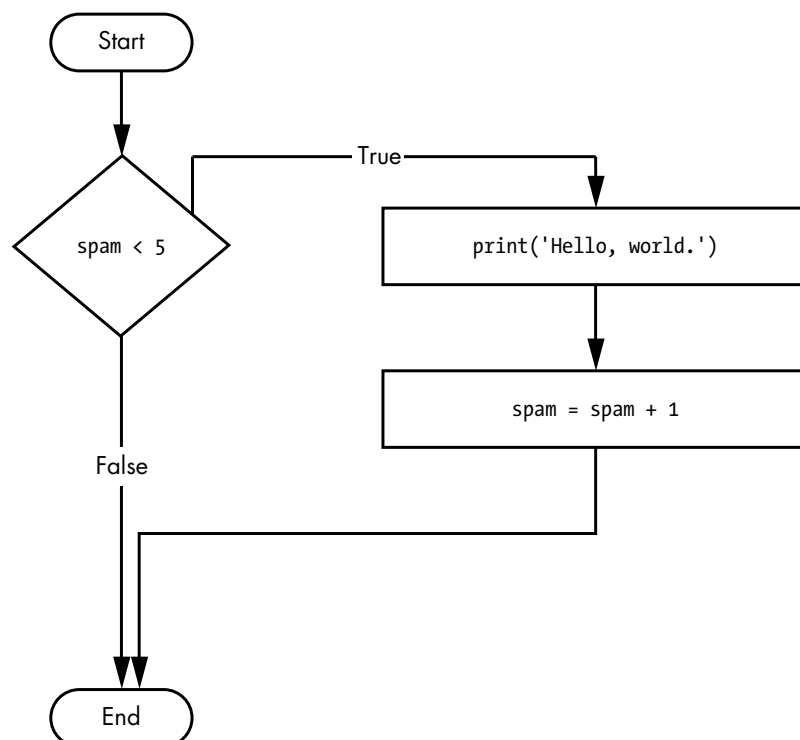

Figure 2-9: The flowchart for the `if` statement code

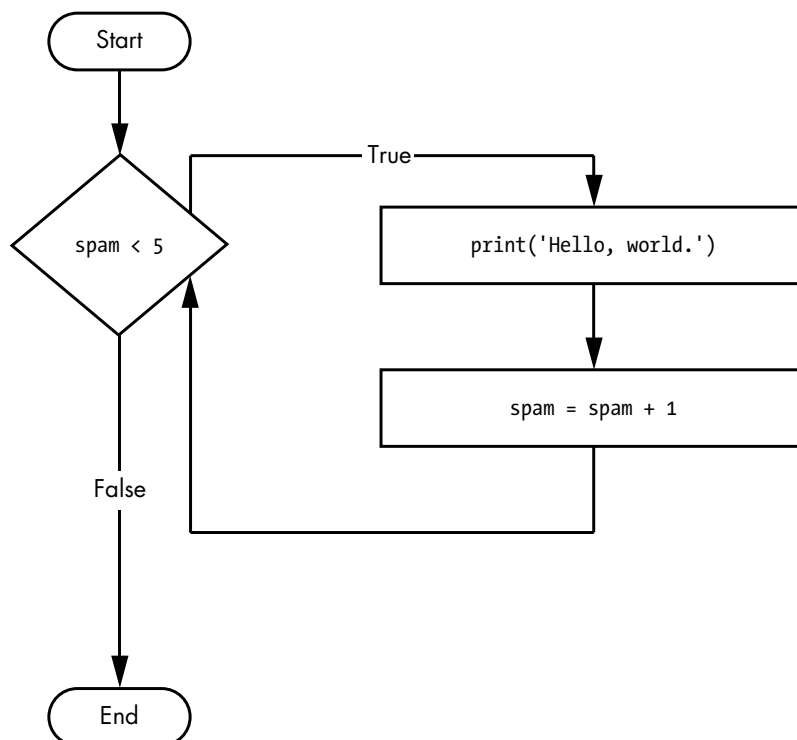

Figure 2-10: The flowchart for the *while* statement code

The code with the *if* statement checks the condition, and it prints *Hello, world.* only once if that condition is true. The code with the *while* loop, on the other hand, will print it five times. It stops after five prints because the integer in *spam* is incremented by one at the end of each loop iteration, which means that the loop will execute five times before *spam < 5* is False.

In the *while* loop, the condition is always checked at the start of each *iteration* (that is, each time the loop is executed). If the condition is True, then the clause is executed, and afterward, the condition is checked again. The first time the condition is found to be False, the *while* clause is skipped.

An Annoying while Loop

Here's a small example program that will keep asking you to type, literally, **your name**. Select **File ▶ New Window** to open a new file editor window, enter the following code, and save the file as *yourName.py*:

```

❶ name = ''
❷ while name != 'your name':
    print('Please type your name.')
❸     name = input()
❹ print('Thank you!')
  
```

First, the program sets the *name* variable ❶ to an empty string. This is so that the *name != 'your name'* condition will evaluate to True and the program execution will enter the *while* loop's clause ❷.

The code inside this clause asks the user to type their name, which is assigned to the `name` variable ❸. Since this is the last line of the block, the execution moves back to the start of the `while` loop and reevaluates the condition. If the value in `name` is *not equal* to the string `'your name'`, then the condition is `True`, and the execution enters the `while` clause again.

But once the user types **your name**, the condition of the `while` loop will be `'your name' != 'your name'`, which evaluates to `False`. The condition is now `False`, and instead of the program execution reentering the `while` loop's clause, it skips past it and continues running the rest of the program ❹. Figure 2-11 shows a flowchart for the `yourName.py` program.

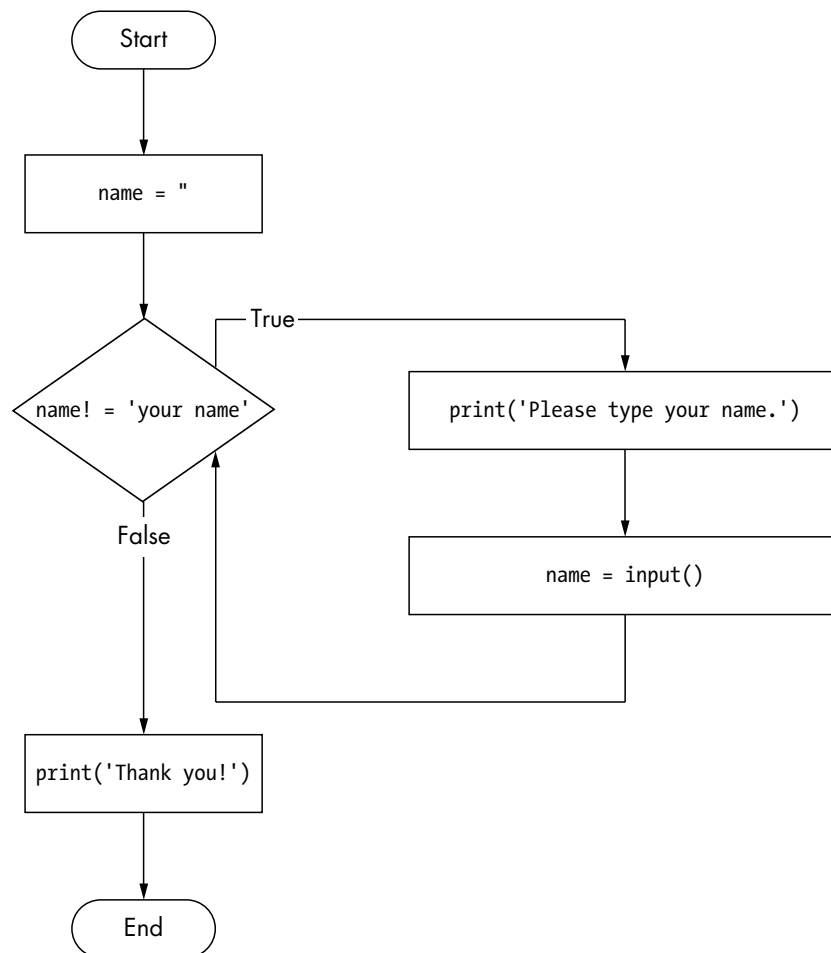

Figure 2-11: A flowchart of the `yourName.py` program

Now, let's see `yourName.py` in action. Press **F5** to run it, and enter something other than **your name** a few times before you give the program what it wants.

```
Please type your name.  
A1  
Please type your name.  
Albert
```

```
Please type your name.  
%#@#%*(^&!!!  
Please type your name.  
your name  
Thank you!
```

If you never enter **your name**, then the `while` loop's condition will never be `False`, and the program will just keep asking forever. Here, the `input()` call lets the user enter the right string to make the program move on. In other programs, the condition might never actually change, and that can be a problem. Let's look at how you can break out of a `while` loop.

***break* Statements**

There is a shortcut to getting the program execution to break out of a `while` loop's clause early. If the execution reaches a `break` statement, it immediately exits the `while` loop's clause. In code, a `break` statement simply contains the `break` keyword.

Pretty simple, right? Here's a program that does the same thing as the previous program, but it uses a `break` statement to escape the loop. Enter the following code, and save the file as *yourName2.py*:

```
❶ while True:  
    print('Please type your name.')  
❷    name = input()  
❸    if name == 'your name':  
❹        break  
❺ print('Thank you!')
```

The first line ❶ creates an *infinite loop*; it is a `while` loop whose condition is always `True`. (The expression `True`, after all, always evaluates down to the value `True`.) The program execution will always enter the loop and will exit it only when a `break` statement is executed. (An infinite loop that *never* exits is a common programming bug.)

Just like before, this program asks the user to type **your name** ❷. Now, however, while the execution is still inside the `while` loop, an `if` statement gets executed ❸ to check whether `name` is equal to `your name`. If this condition is `True`, the `break` statement is run ❹, and the execution moves out of the loop to `print('Thank you!')` ❺. Otherwise, the `if` statement's clause with the `break` statement is skipped, which puts the execution at the end of the `while` loop. At this point, the program execution jumps back to the start of the `while` statement ❶ to recheck the condition. Since this condition is merely the `True` Boolean value, the execution enters the loop to ask the user to type **your name** again. See Figure 2-12 for the flowchart of this program.

Run *yourName2.py*, and enter the same text you entered for *yourName.py*. The rewritten program should respond in the same way as the original.

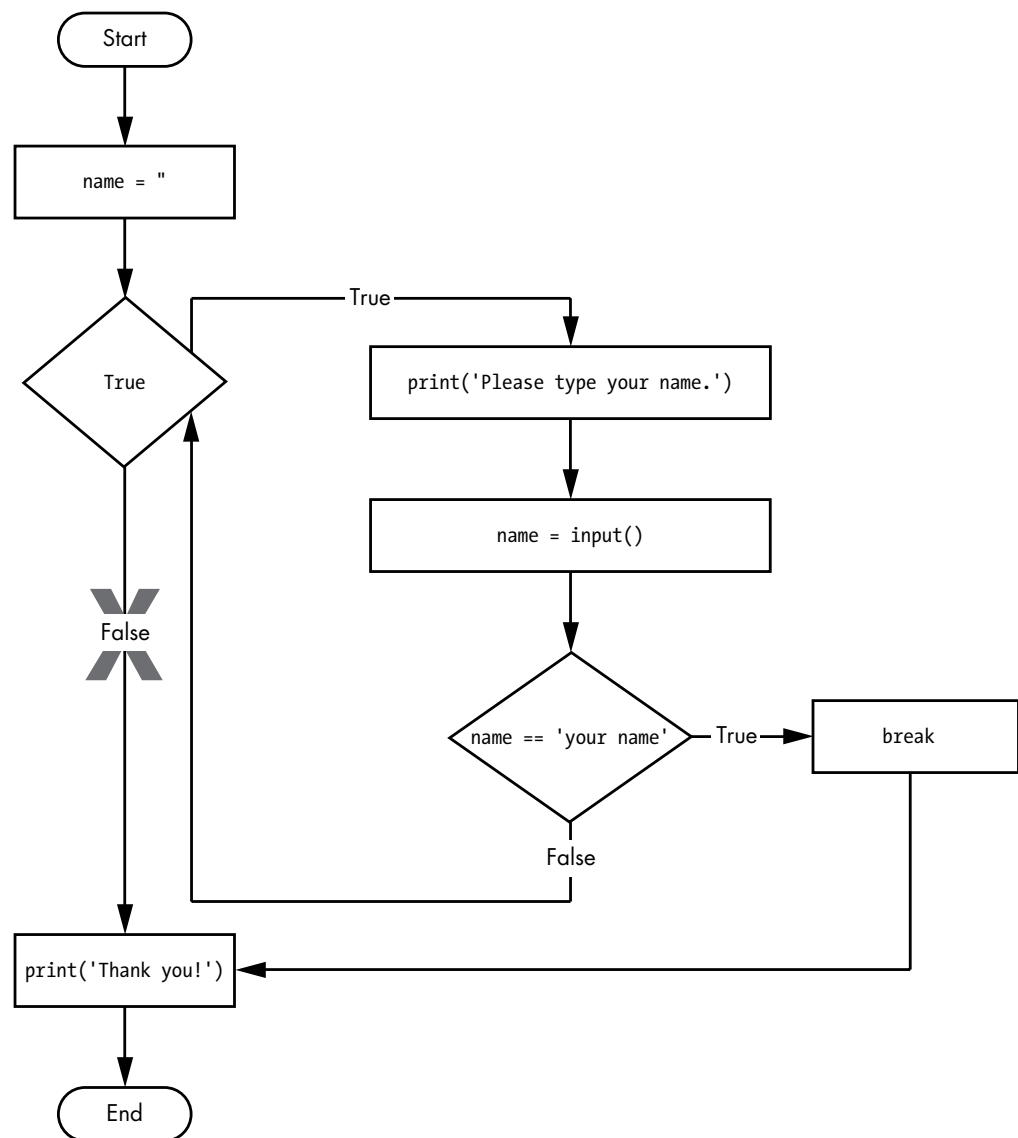

Figure 2-12: The flowchart for the `yourName2.py` program with an infinite loop. Note that the X path will logically never happen because the loop condition is always `True`.

continue Statements

Like `break` statements, `continue` statements are used inside loops. When the program execution reaches a `continue` statement, the program execution immediately jumps back to the start of the loop and reevaluates the loop's condition. (This is also what happens when the execution reaches the end of the loop.)

TRAPPED IN AN INFINITE LOOP?

If you ever run a program that has a bug causing it to get stuck in an infinite loop, press **CTRL-C**. This will send a `KeyboardInterrupt` error to your program and cause it to stop immediately. To try it, create a simple infinite loop in the file editor, and save it as *infinitemloop.py*.

```
while True:
    print('Hello world!')
```

When you run this program, it will print `Hello world!` to the screen forever, because the `while` statement's condition is always `True`. In IDLE's interactive shell window, there are only two ways to stop this program: press **CTRL-C** or select **Shell ▶ Restart Shell** from the menu. **CTRL-C** is handy if you ever want to terminate your program immediately, even if it's not stuck in an infinite loop.

Let's use `continue` to write a program that asks for a name and password. Enter the following code into a new file editor window and save the program as *swordfish.py*.

```
while True:
    print('Who are you?')
    name = input()
    ❶ if name != 'Joe':
    ❷     continue
    print('Hello, Joe. What is the password? (It is a fish.)')
    ❸ password = input()
    if password == 'swordfish':
    ❹     break
    ❺ print('Access granted.')
```

If the user enters any name besides Joe ❶, the `continue` statement ❷ causes the program execution to jump back to the start of the loop. When it reevaluates the condition, the execution will always enter the loop, since the condition is simply the value `True`. Once they make it past that `if` statement, the user is asked for a password ❸. If the password entered is `swordfish`, then the `break` statement ❹ is run, and the execution jumps out of the `while` loop to print `Access granted` ❺. Otherwise, the execution continues to the end of the `while` loop, where it then jumps back to the start of the loop. See Figure 2-13 for this program's flowchart.

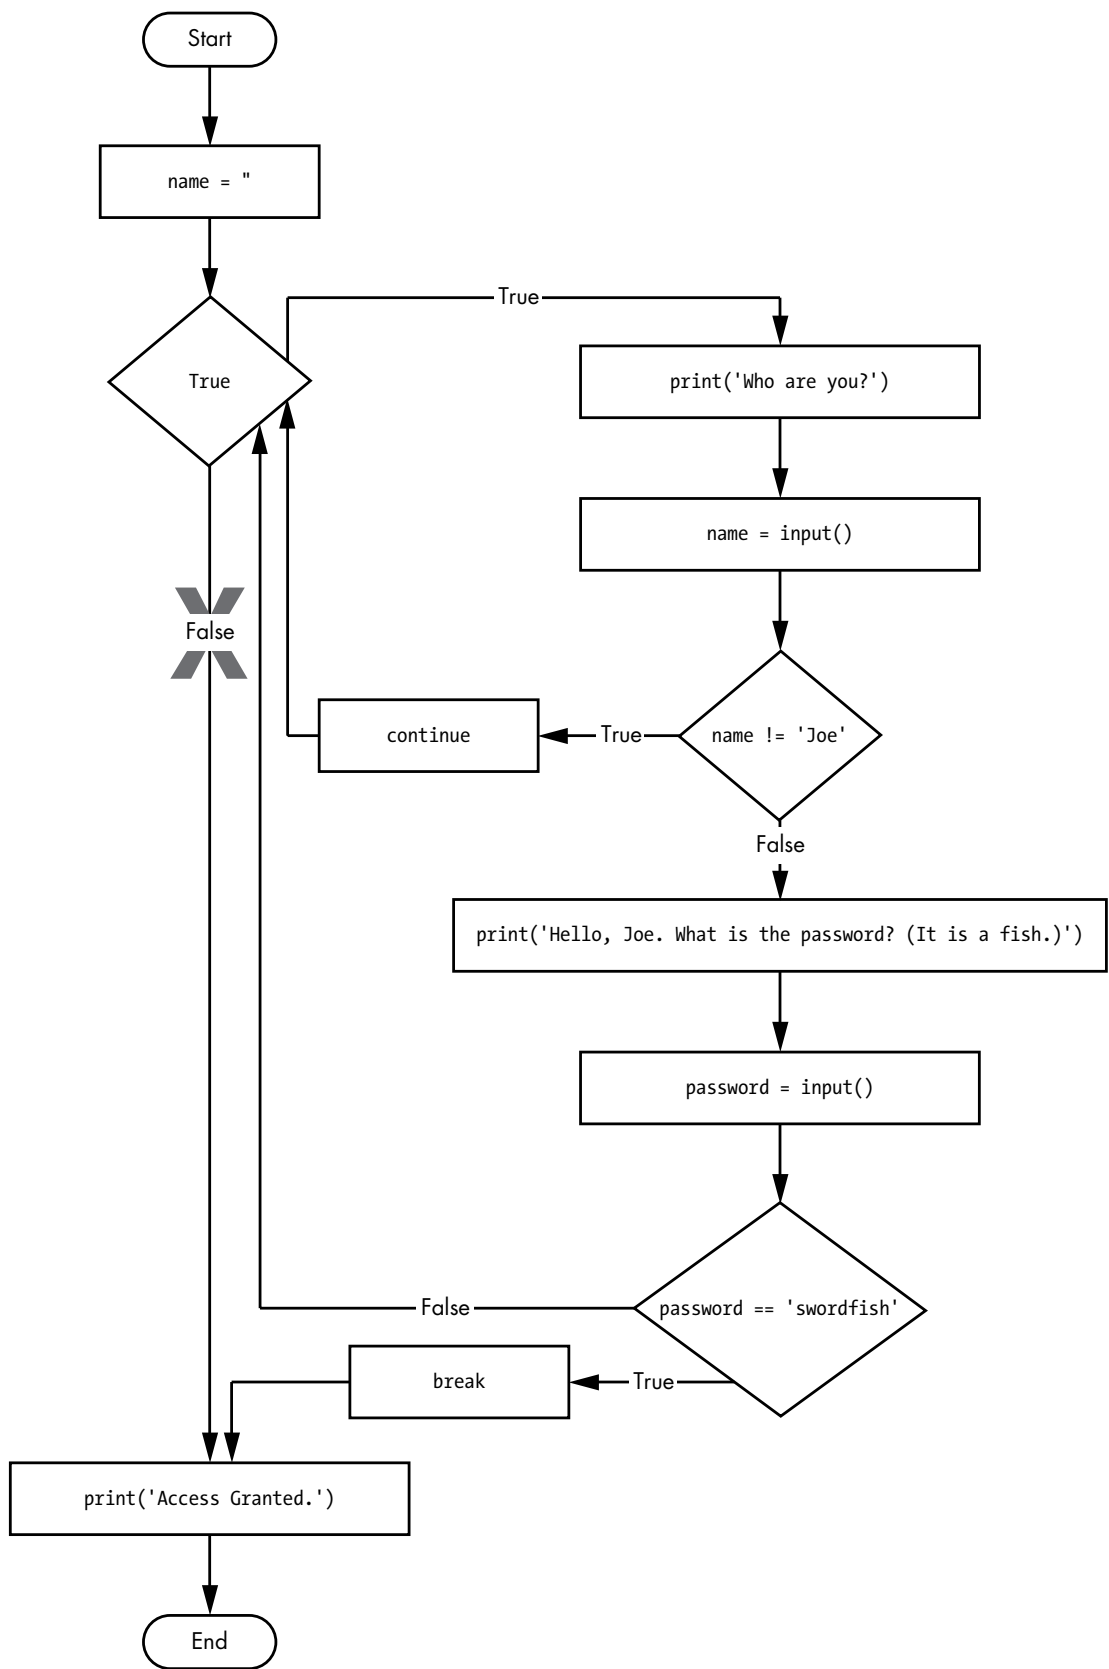

Figure 2-13: A flowchart for `swordfish.py`. The X path will logically never happen because the loop condition is always `True`.

"TRUTHY" AND "FALSEY" VALUES

There are some values in other data types that conditions will consider equivalent to True and False. When used in conditions, 0, 0.0, and '' (the empty string) are considered False, while all other values are considered True. For example, look at the following program:

```
name = ''
while not name:❶
    print('Enter your name:')
    name = input()
print('How many guests will you have?')
numOfGuests = int(input())
if numOfGuests:❷
    print('Be sure to have enough room for all your guests.')❸
print('Done')
```

If the user enters a blank string for name, then the while statement's condition will be True ❶, and the program continues to ask for a name. If the value for numOfGuests is not 0 ❷, then the condition is considered to be True, and the program will print a reminder for the user ❸.

You could have typed `not name != ''` instead of `not name`, and `numOfGuests != 0` instead of `numOfGuests`, but using the truthy and falsey values can make your code easier to read.

Run this program and give it some input. Until you claim to be Joe, it shouldn't ask for a password, and once you enter the correct password, it should exit.

```
Who are you?
I'm fine, thanks. Who are you?
Who are you?
Joe
Hello, Joe. What is the password? (It is a fish.)
Mary
Who are you?
Joe
Hello, Joe. What is the password? (It is a fish.)
swordfish
Access granted.
```

for Loops and the range() Function

The while loop keeps looping while its condition is True (which is the reason for its name), but what if you want to execute a block of code only a certain number of times? You can do this with a for loop statement and the range() function.

In code, a for statement looks something like `for i in range(5):` and always includes the following:

- The for keyword
- A variable name
- The in keyword
- A call to the `range()` method with up to three integers passed to it
- A colon
- Starting on the next line, an indented block of code (called the for clause)

Let's create a new program called *fiveTimes.py* to help you see a for loop in action.

```
print('My name is')
for i in range(5):
    print('Jimmy Five Times (' + str(i) + ')')
```

The code in the for loop's clause is run five times. The first time it is run, the variable `i` is set to 0. The `print()` call in the clause will print `Jimmy Five Times (0)`. After Python finishes an iteration through all the code inside the for loop's clause, the execution goes back to the top of the loop, and the for statement increments `i` by one. This is why `range(5)` results in five iterations through the clause, with `i` being set to 0, then 1, then 2, then 3, and then 4. The variable `i` will go up to, but will not include, the integer passed to `range()`. Figure 2-14 shows a flowchart for the *fiveTimes.py* program.

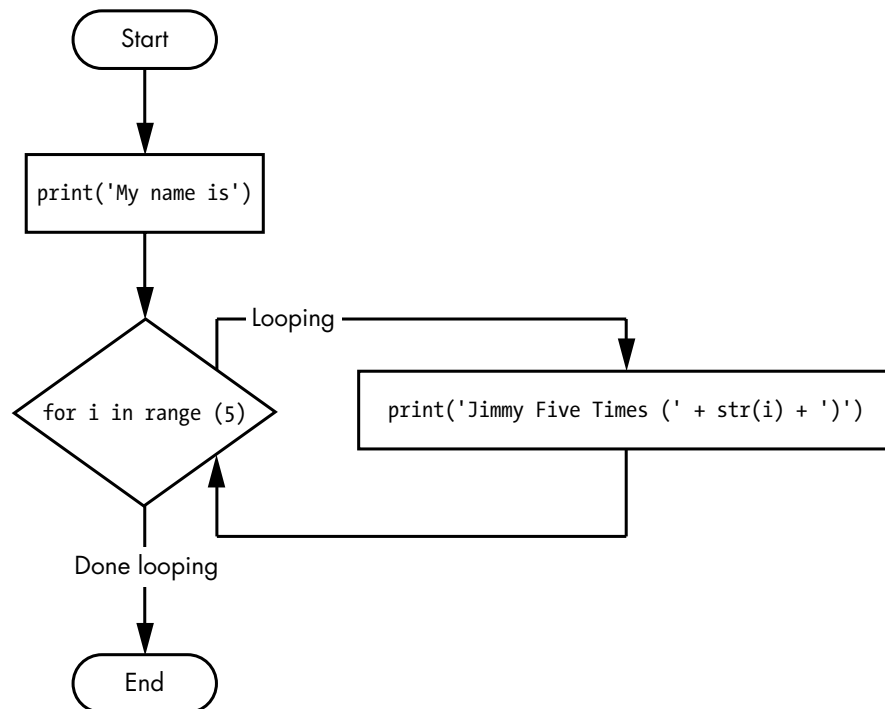

Figure 2-14: The flowchart for *fiveTimes.py*

When you run this program, it should print Jimmy Five Times followed by the value of `i` five times before leaving the `for` loop.

```
My name is
Jimmy Five Times (0)
Jimmy Five Times (1)
Jimmy Five Times (2)
Jimmy Five Times (3)
Jimmy Five Times (4)
```

NOTE

You can use `break` and `continue` statements inside for loops as well. The `continue` statement will continue to the next value of the `for` loop's counter, as if the program execution had reached the end of the loop and returned to the start. In fact, you can use `continue` and `break` statements only inside `while` and `for` loops. If you try to use these statements elsewhere, Python will give you an error.

As another `for` loop example, consider this story about the mathematician Karl Friedrich Gauss. When Gauss was a boy, a teacher wanted to give the class some busywork. The teacher told them to add up all the numbers from 0 to 100. Young Gauss came up with a clever trick to figure out the answer in a few seconds, but you can write a Python program with a `for` loop to do this calculation for you.

```
❶ total = 0
❷ for num in range(101):
❸     total = total + num
❹ print(total)
```

The result should be 5,050. When the program first starts, the `total` variable is set to 0 ❶. The `for` loop ❷ then executes `total = total + num` ❸ 100 times. By the time the loop has finished all of its 100 iterations, every integer from 0 to 100 will have been added to `total`. At this point, `total` is printed to the screen ❹. Even on the slowest computers, this program takes less than a second to complete.

(Young Gauss figured out that there were 50 pairs of numbers that added up to 100: 1 + 99, 2 + 98, 3 + 97, and so on, until 49 + 51. Since 50×100 is 5,000, when you add that middle 50, the sum of all the numbers from 0 to 100 is 5,050. Clever kid!)

An Equivalent `while` Loop

You can actually use a `while` loop to do the same thing as a `for` loop; `for` loops are just more concise. Let's rewrite *fiveTimes.py* to use a `while` loop equivalent of a `for` loop.

```
print('My name is')
i = 0
while i < 5:
    print('Jimmy Five Times (' + str(i) + ')')
    i = i + 1
```

If you run this program, the output should look the same as the *fiveTimes.py* program, which uses a for loop.

The Starting, Stopping, and Stepping Arguments to range()

Some functions can be called with multiple arguments separated by a comma, and range() is one of them. This lets you change the integer passed to range() to follow any sequence of integers, including starting at a number other than zero.

```
for i in range(12, 16):  
    print(i)
```

The first argument will be where the for loop's variable starts, and the second argument will be up to, but not including, the number to stop at.

```
12  
13  
14  
15
```

The range() function can also be called with three arguments. The first two arguments will be the start and stop values, and the third will be the *step argument*. The step is the amount that the variable is increased by after each iteration.

```
for i in range(0, 10, 2):  
    print(i)
```

So calling range(0, 10, 2) will count from zero to eight by intervals of two.

```
0  
2  
4  
6  
8
```

The range() function is flexible in the sequence of numbers it produces for for loops. *For* example (I never apologize for my puns), you can even use a negative number for the step argument to make the for loop count down instead of up.

```
for i in range(5, -1, -1):  
    print(i)
```

Running a for loop to print i with range(5, -1, -1) should print from five down to zero.

```
5  
4
```

Importing Modules

All Python programs can call a basic set of functions called *built-in functions*, including the `print()`, `input()`, and `len()` functions you've seen before. Python also comes with a set of modules called the *standard library*. Each module is a Python program that contains a related group of functions that can be embedded in your programs. For example, the `math` module has mathematics-related functions, the `random` module has random number-related functions, and so on.

Before you can use the functions in a module, you must import the module with an `import` statement. In code, an `import` statement consists of the following:

- The `import` keyword
- The name of the module
- Optionally, more module names, as long as they are separated by commas

Once you import a module, you can use all the cool functions of that module. Let's give it a try with the `random` module, which will give us access to the `random.randint()` function.

Enter this code into the file editor, and save it as *printRandom.py*:

```
import random
for i in range(5):
    print(random.randint(1, 10))
```

When you run this program, the output will look something like this:

4
1
8
4
1

The `random.randint()` function call evaluates to a random integer value between the two integers that you pass it. Since `randint()` is in the `random` module, you must first type **random.** in front of the function name to tell Python to look for this function inside the `random` module.

Here's an example of an `import` statement that imports four different modules:

```
import random, sys, os, math
```

Now we can use any of the functions in these four modules. We'll learn more about them later in the book.

from import Statements

An alternative form of the `import` statement is composed of the `from` keyword, followed by the module name, the `import` keyword, and a star; for example, `from random import *`.

With this form of `import` statement, calls to functions in `random` will not need the `random.` prefix. However, using the full name makes for more readable code, so it is better to use the normal form of the `import` statement.

Ending a Program Early with `sys.exit()`

The last flow control concept to cover is how to terminate the program. This always happens if the program execution reaches the bottom of the instructions. However, you can cause the program to terminate, or exit, by calling the `sys.exit()` function. Since this function is in the `sys` module, you have to import `sys` before your program can use it.

Open a new file editor window and enter the following code, saving it as *exitExample.py*:

```
import sys

while True:
    print('Type exit to exit.')
    response = input()
    if response == 'exit':
        sys.exit()
    print('You typed ' + response + '.')
```

Run this program in IDLE. This program has an infinite loop with no `break` statement inside. The only way this program will end is if the user enters `exit`, causing `sys.exit()` to be called. When `response` is equal to `exit`, the program ends. Since the `response` variable is set by the `input()` function, the user must enter `exit` in order to stop the program.

Summary

By using expressions that evaluate to `True` or `False` (also called *conditions*), you can write programs that make decisions on what code to execute and what code to skip. You can also execute code over and over again in a loop while a certain condition evaluates to `True`. The `break` and `continue` statements are useful if you need to exit a loop or jump back to the start.

These flow control statements will let you write much more intelligent programs. There's another type of flow control that you can achieve by writing your own functions, which is the topic of the next chapter.

Practice Questions

1. What are the two values of the Boolean data type? How do you write them?
2. What are the three Boolean operators?
3. Write out the truth tables of each Boolean operator (that is, every possible combination of Boolean values for the operator and what they evaluate to).
4. What do the following expressions evaluate to?

```
(5 > 4) and (3 == 5)
not (5 > 4)
(5 > 4) or (3 == 5)
not ((5 > 4) or (3 == 5))
(True and True) and (True == False)
(not False) or (not True)
```

5. What are the six comparison operators?
6. What is the difference between the equal to operator and the assignment operator?
7. Explain what a condition is and where you would use one.
8. Identify the three blocks in this code:

```
spam = 0
if spam == 10:
    print('eggs')
    if spam > 5:
        print('bacon')
    else:
        print('ham')
    print('spam')
print('spam')
```

9. Write code that prints Hello if 1 is stored in spam, prints Howdy if 2 is stored in spam, and prints Greetings! if anything else is stored in spam.
10. What can you press if your program is stuck in an infinite loop?
11. What is the difference between break and continue?
12. What is the difference between range(10), range(0, 10), and range(0, 10, 1) in a for loop?
13. Write a short program that prints the numbers 1 to 10 using a for loop. Then write an equivalent program that prints the numbers 1 to 10 using a while loop.
14. If you had a function named bacon() inside a module named spam, how would you call it after importing spam?

Extra credit: Look up the round() and abs() functions on the Internet, and find out what they do. Experiment with them in the interactive shell.
